(Received 31 July 2016; published 16 December 2016)

#### Abstract

The quantum electrodynamics (QED) corrections are directly incorporated into the most accurate treatment of the correlation corrections for ions with complex electronic structure of interest to metrology and tests of fundamental physics. We compared the performance of four different QED potentials for various systems to access the accuracy of QED calculations and to make a prediction of highly charged ion properties urgently needed for planning future experiments. We find that all four potentials give consistent and reliable results for ions of interest. For the strongly bound electrons, the nonlocal potentials are more accurate than the local potential.

DOI: 10.1103/PhysRevLett.117.253001

In 2015, a sympathetic cooling of $\mathrm{Ar}^{13+}$ with laser cooled $\mathrm{Be}^{+}$ions was demonstrated [1], elevating highly charged ions (HCI) to the realm of applications previously limited to singly charged ions currently used for atomic clocks [2], quantum information [3], and other applications requiring laser cooling and trapping. Optical transitions in heavy many-electron HCIs have been recently proposed for the development of ultraprecision atomic clocks and tests of fundamental physics [4-8]. The experimental work toward the realization of these proposals has already started [9], but locating these ultranarrow optical transitions has proven to be very difficult. For most of these ions, no experimental data exist and identification of their complicated atomic spectra is a very difficult task unless accurate theoretical predictions are available.

The required calculations also present a difficult task due to very large cancellations of the energies of upper and lower states. Since the ions of interest have a relatively low degree of ionization, $8^{+}$to $18^{+}$, high-order electron correlation, Breit interaction, and radiative quantum electrodynamic (QED) corrections are all important, with the cancellation of these contributions making accurate computations even more difficult [7]. As a result, it has become urgent to accurately include QED corrections in the calculations of the electronic structure of such many-electron ions, and evaluate the uncertainty associated with the QED treatment.

Nonempirical calculations of radiative corrections using the QED perturbation theory for many-electron systems are extremely complicated and time consuming. To date, allorder high-accuracy calculations can be performed only for highly charged few-electron ions (see, e.g., [10-23] and references therein), or using the same perturbative methods for many-electron systems, but with an effective screening potential [24-29]. This potential can be constructed using Dirac-Hartree and Dirac-Fock-Slater methods, or density
functional theory in the local density approximation. Ab initio QED methods are too complicated to be directly incorporated into the Dirac-Coulomb-Breit many-electron calculations. For this reason, numerous attempts have been undertaken to propose simple methods for incorporating QED corrections into the many-configuration Dirac-Fock, configuration interaction Dirac-Fock, and relativistic manybody perturbation theory (MBPT) codes using different QED model potentials (see, e.g., [30-41] and references therein).

Present work resolves the problem of accurate treatment of quantum electrodynamic corrections for many-electron ions of interest to metrology and tests of fundamental physics. For the first time, the QED corrections are directly incorporated into the most accurate treatment of the correlation corrections for multivalent atoms: a high-precision relativistic hybrid approach that combines configuration interaction (CI) and a linearized variant of the single-double coupled-cluster method, generally referred to as the CI + all-order approach [42]. We have applied our method to HCIs of interest to metrology, carrying out all calculations with four different QED potentials, and evaluated the accuracy of the QED results. Our work presents the first systematic study of the QED accuracy for heavy multivalent HCIs and answers the following questions: (1) how accurate are various model potentials; (2) how much the QED correction in HCIs depends on the version of the model potential being used; (3) how important is it to include the QED corrections when constructing the basis set orbitals; (4) how do QED contributions in such many-electron systems depend on the treatment of the correlation corrections. Using our new method, we give a new prediction for the $5 f 6 p^{22} F_{5 / 2}-5 f^{2} 6 p^{2} F_{9 / 2}$ clock transitions energy of $\mathrm{Cf}^{15+}$, which is particularly well suited for the search for variation of the fine-structure constant [8].

Our point of departure is the Dirac-Fock-Breit method used to generate core and valence electronic orbitals. To form a complete finite basis set for all coupled-cluster calculations, we generate a large $(N>400)$ set of virtual orbitals. The QED correction is incorporated into the basis set orbital via the model QED potentials described below. Then, we use the linearized coupled-cluster approach to construct an effective Hamiltonian that includes core-core and core-valence corrections [42]. This procedure includes dominant classes of the perturbation theory terms involving core excitations to all orders. In constructing the effective Hamiltonian, all core-core and core-valence single and double excitations to all basis set orbitals are included. The QED corrections are added to the one-electron matrix elements of the effective Hamiltonian, which also includes Dirac-Fock-Breit potential of the core and Coulomb-Breit interactions of the valence electrons. An atomic spectrum is found by diagonalization of the effective Hamiltonian in the configurational space, and the matrix elements for various (electric-dipole, magnetic-dipole, hyperfine, etc.) operators are obtained using the resulting wave functions. Our configuration space includes [ $21 s p d f 18 g$ ] orbitals. The CI space only has to include the valence electrons since the core excitations from all core shells are already included into the effective Hamiltonian. Therefore, the configuration space can be made effectively complete for up to four valence electrons. An algorithm for the efficient selection of dominant configurations for three-four valence electrons and the corresponding accuracy of the CI calculations has been discussed in detail in [43].

Since the main issue in the evaluation of the accuracy of the QED is the question of which QED model potential gives the best accuracy, we included four different QED potentials, which differ in their treatment of the self-energy contribution. We carried out all calculations and accuracy tests for all four potentials.

The one-electron QED potential is separated into three contributions:

$$
\begin{equation*}
V^{\mathrm{QED}}=V^{\mathrm{SE}}+V_{\mathrm{Uehl}}+V_{\mathrm{WK}}, \tag{1}
\end{equation*}
$$

where $V^{\text {SE }}$ is the self-energy operator, $V_{\text {Uehl }}$ and $V_{\text {WK }}$ are the Uehling and Wichmann-Kroll parts of the vacuum polarization, respectively. Both $V_{\text {Uehl }}$ and $V_{\text {WK }}$ are local potentials, so their treatment is rather straightforward and is the same in all four versions of the calculations. The Uehling potential can be evaluated by a direct numerical integration of the well-known formula [44], or, more easily, by using the approximate formulas from Ref. [45]. A direct numerical evaluation of the Wichmann-Kroll potential $V_{\mathrm{WK}}$ is rather complicated. For the purpose of the present work, it is sufficient to use the approximate formulas for the pointlike nucleus from Ref. [46]. We label four QED methods used to include the self-energy $M 1-M 4$ and briefly describe their main features below.

QED potential M1.-Following $[39,47]$ we approximate the one-electron SE operator as the sum of local $V_{\mathrm{loc}}^{\mathrm{SE}}$ and nonlocal $V_{\mathrm{nl}}$ potentials

$$
\begin{equation*}
V^{\mathrm{SE}}=V_{\mathrm{loc}}^{\mathrm{SE}}+V_{\mathrm{nl}} \tag{2}
\end{equation*}
$$

where nonlocal potential is given in a separable form

$$
\begin{equation*}
V_{\mathrm{nl}}=\sum_{i, k=1}^{n}\left|\phi_{i}\right\rangle B_{i k}\left\langle\phi_{k}\right| . \tag{3}
\end{equation*}
$$

Here, $\phi_{i}$ are so-called projector functions. The choice of these functions depends on the method of construction of the nonlocal potential $V_{\mathrm{nl}}$ and is described in details in [39]. The constants $B_{i k}$ are chosen so that the matrix elements of the model operator $V_{i k}^{\mathrm{SE}}$ calculated with hydrogenlike wave functions $\psi_{i}$ have to be equal to matrix elements $Q_{i k}$ of the symmetrized exact one-loop energy-dependent SE operator $\Sigma(\varepsilon)$ [48]:

$$
\begin{equation*}
\left\langle\psi_{i}\right| V^{\mathrm{SE}}\left|\psi_{k}\right\rangle=Q_{i k}=\frac{1}{2}\left[\Sigma\left(\varepsilon_{i}\right)+\Sigma\left(\varepsilon_{k}\right)\right] \tag{4}
\end{equation*}
$$

Introducing two matrices $\Delta Q_{i k}=Q_{i k}-\left\langle\psi_{i}\right| V_{\mathrm{loc}}^{\mathrm{SE}}\left|\psi_{k}\right\rangle$ and $D_{i k}=\left\langle\phi_{i} \mid \psi_{k}\right\rangle$, we find that

$$
\begin{equation*}
B_{i k}=\sum_{j, l=1}^{n}\left(D^{-1}\right)_{j i}\left\langle\psi_{j}\right| \Delta Q_{j l}\left|\psi_{l}\right\rangle\left(D^{-1}\right)_{l k} \tag{5}
\end{equation*}
$$

The local part of the SE potential in [39] was taken to be

$$
\begin{equation*}
V_{\mathrm{loc}, k}^{\mathrm{SE}}(r)=A_{k} \exp \left(-r / \chi_{C}\right), \tag{6}
\end{equation*}
$$

where the constant $A_{\kappa}$ is chosen to reproduce the SE shift for the lowest energy level at the given $\kappa$ in the corresponding $H$-like ion, and $\chi_{C}=\hbar /(m c)$. The QEDMOD computation code based on this method was published in Ref. [47].

QED potential M2.-In this approach we use the same equations (2), (3), (5) to construct the SE potential, but use radiative potential developed in $[33,49]$ for the local part. In [33], the self-energy part of the total radiative potential is divided into three terms:

$$
\begin{equation*}
V_{\mathrm{loc}}^{\mathrm{SE}}=\Phi_{\mathrm{rad}}=\Phi_{\mathrm{mag}}+\Phi_{\mathrm{lf}}+\Phi_{\mathrm{hf}} \tag{7}
\end{equation*}
$$

where the potentials $\Phi_{\mathrm{mag}}, \Phi_{\mathrm{lf}}$, and $\Phi_{\mathrm{hf}}$ are referred to as the magnetic form factor, the low- and high-frequency parts of the electric form factor, respectively, according to [33]. The expressions for these potentials are given by Eqs. (7, 9, 10) in [33]. Then, we obtain for the total SE potential

$$
\begin{equation*}
V^{\mathrm{SE}}=\Phi_{\mathrm{rad}}+\sum_{i, k=1}^{n}\left|\phi_{i}\right\rangle B_{i k}\left\langle\phi_{k}\right| . \tag{8}
\end{equation*}
$$

The electric form factor contains some fitting parameters to reproduce the SE corrections for $5 s$ and $5 p$ states of heavy $H$-like ions. However, the local radiative potential $\Phi_{\text {rad }}$ gives the SE contribution for the $1 s$ state with only $10 \%$

TABLE I. The self-energy function $F(\alpha Z)$ for the ground states of neutral alkali metals calculated using the methods $M 1-M 4$. The row "Exact" presents $a b$ initio results from Ref. [24].

accuracy [33] (see method M3 below). The SE potential (8) which contains the nonlocal part in addition to the local radiative potential reproduces the low lying SE corrections of the $H$-like ions exactly.

QED potential M3 (local radiation potential).-Here, we neglect the nonlocal term in (8) and use local radiative potential $V^{\mathrm{SE}}=V_{\mathrm{loc}}^{\mathrm{SE}}=\Phi_{\mathrm{rad}}$ from Eq. (7) as a full SE oneelectron potential introduced in [33]. This radiative potential was widely used in many-electron calculations, for example, see $[34,38,41,50]$, and references therein. Note that this local potential was optimized for weakly bound valence states of heavy neutral atoms and may be less accurate for strongly bound ionic, or core states.

QED potential M4.-This approach developed in [36] is similar to the method $M 2$, with the SE operator given by Eq. (8), but using a different choice of the projector functions $B_{i k}^{\prime}$ and only diagonal matrix elements $Q_{i i}$.

To assess the accuracy of these potentials, we compare the SE values obtained using $M 1, M 2, M 3$, and $M 4$ methods with the $a b$ initio calculations of Refs. [24] and [28], respectively, to which we refer as "exact". Calculations of the SE shifts in Refs. [24,28] were performed with the local potential $V_{\text {eff }}(r)$ :
$V_{\mathrm{eff}}(r)=V_{\mathrm{nuc}}(r)-\int_{0}^{\infty} d r^{\prime} \frac{\rho\left(r^{\prime}\right)}{r_{>}}+x_{\alpha}\left[\frac{81}{32 \pi^{2}} r \rho(r)\right]^{1 / 3}$,
where $V_{\text {nuc }}(r)$ is nuclear potential and $\rho(r)$ is the total electron charge density. The choice of $x_{\alpha}=2 / 3$ corresponds to the Kohn-Sham potential, and $x_{\alpha}=1$ is the Dirac-Fock-Slater potential.

Our data were obtained by averaging the SE operator $V^{\mathrm{SE}}$ with the wave function of the valence state determined from the Dirac equation with the potential $V_{\text {eff }}(r)$.

In Table I, the SE shifts for the ground $n s$ states of the neutral alkali atoms are given in terms of function $F(\alpha Z)$, defined by

$$
\begin{equation*}
\Delta E^{\mathrm{SE}}=\frac{\alpha}{\pi} \frac{(\alpha Z)^{4}}{n^{3}} F(\alpha Z) m c^{2} \tag{10}
\end{equation*}
$$

In Table II we present the SE corrections calculated for the $4 s-4 p$ and $4 p-4 d$ transition energies of Cu -like ions. Tables I and II illustrate that the SE shifts obtained using M1, M2,

and M4 methods are in very good agreement with exact results, at the level of $1 \%$ or better for the $M 1$ and $M 2$ QED potentials. We find 5\%-10\% discrepancies between the data calculated using the local radiative potential (method M3) and exact values. We note that method M3 was recently modified in Ref. [41], where more complicated and accurate finite size correction to the radiative potential and additional fitting for the $d$ states were introduced. Comparisons for all alkali-metal atoms and other Cu -like ions are given in the Supplemental Material [51].

TABLE III. A comparison of the QED corrections obtained using methods $M 1-M 4$ to the energies of $\mathrm{Ba}^{8+}, \mathrm{Eu}^{14+}$, and $\mathrm{Cf}^{15+}$ calculated in the CI + all-order approach $\left(\mathrm{cm}^{-1}\right)$. The column labeled $M 1^{\prime}$ gives results of the CI + MBPT calculation. The column labeled CI-M1 gives results of the calculation where QED potential was included only in CI Hamiltonian. The first variant of the QED potential (M1) was used in both of these calculations.

TABLE IV. Transition energies $\left(\mathrm{cm}^{-1}\right)$ for $\mathrm{Ba}^{8+}, \mathrm{Eu}^{14+}$, and $\mathrm{Cf}^{15+}$ calculated using the $\mathrm{CI}+$ all-order method and $M 1$ version of QED potential. Experimental results for $\mathrm{Ba}^{8+}$ are from Ref. [57]. Columns QED, $3 e$, and Total present QED corrections, contribution of the effective three-electron interactions [56], and final theoretical values, respectively. The columns "Conf.", "Expt.", and "Diff." denote the list of configurations, experimental values, and relative difference of the theory with the experiment in percent respectively.

We selected three representative highly charge ions with different electronic configurations as the test cases for our method. All of these ions were included in the studies of the applications of HCIs to the development of clocks and tests of the variation of the fundamental constants [7,8,52,53]. $\mathrm{Ba}^{8+}$ was selected owing to the availability of the experimental values for comparison, $\mathrm{Eu}^{14+}$ was chosen as the test case with the $f^{3}$ configuration, and $\mathrm{Cf}^{15+}$ has the largest sensitivity to the alpha variation in a system which satisfies all the requirements for the development of accurate optical atomic clocks [8]. To separate the QED corrections, the $\mathrm{CI}+$ all-order computations were carried out with and without the QED corrections and the difference was taken to be the QED contribution.

A comparison of the QED corrections to the energies of $\mathrm{Ba}^{8+}, \mathrm{Eu}^{14+}$, and $\mathrm{Cf}^{15+}$ ions obtained using four QED potentials is given in Table III. We would like to attract the reader's attention to unexpectedly large QED corrections for the $5 f$ state of $\mathrm{Cf}^{15+}$. One expects that the QED corrections for the $4 f$ and $5 f$ orbitals are zero owing to no overlap with the nucleus. However, the addition of the QED potential modifies the Dirac-Fock-Breit self-consistent potential leading to changes of energies of the $5 f$ orbitals. To confirm this, we carried out a separate calculation, including the QED potential only in the CI Hamiltonian, and constructing orbitals with no QED correction. These results are listed in Table III in the column labeled CI-M1. The QED correction for the ground $5 f 6 p^{2}{ }^{2} F_{5 / 2}$ state, $828 \mathrm{~cm}^{-1}$, is close to twice a QED corrections for the $6 p$ states, with zero contribution for the $5 f$ states. Including the QED in the potential used to construct the orbitals both reduces the QED correction for the $6 p$ states and leads to large $\left(\approx-460 \mathrm{~cm}^{-1}\right)$ negative QED correction for the $5 f$ orbital reversing the sign of the total QED correction of the $5 f 6 p^{2}$ configuration.

As we discussed above, both $M 1$ and $M 2$ potentials give results within $1 \%$ of the "exact" ab initio calculation; therefore, we estimate the uncertainty in the QED correction as a
difference of the $M 1$ and $M 2$ results listed in Table III, which does not exceed $12 \mathrm{~cm}^{-1}$. This is far below the uncertainty in the treatment of the Coulomb correlations. Therefore, it is important to explore if QED correction depends on the accuracy of the correlation correction treatment. To answer this question, we carried out the same calculations using the less accurate method that combines CI and MBPT [54,55] approaches. In the CI + MBPT method, an effective Hamiltonian is constructed using the second order of MBPT, omitting all high-order core-core and core-valence correlation corrections included in the $\mathrm{CI}+$ all-order method. $\mathrm{CI}+$ MBPT results are listed in column labeled $M 1^{\prime}$. The differences between the QED contributions calculated in the CI + MBPT and CI-all-order methods are small for $\mathrm{Ba}^{8+}$ and $\mathrm{Eu}^{14+}$, but significant for $J=\frac{7}{2} 5 f 6 p^{2}$ and $5 f^{2} 6 p$ levels of $\mathrm{Cf}^{15+}$. These $J=\frac{7}{2}$ levels are strongly mixed and all-order corrections change weights of $6 p$ and $5 f$ electrons in the many-electron wave function, which affects the total QED correction for the configuration. Therefore, we conclude that incorporation of the QED into the most accurate treatment of the correlation correction is essential for the accurate prediction of the properties of HCIs of interest.

The QED corrections to the energies of $\mathrm{Ba}^{8+}, \mathrm{Eu}^{14+}$, $\mathrm{Cf}^{15+}$ calculated using the $\mathrm{CI}+$ all-order method with the first version of the QED potential are given in Table IV to illustrate the relative size of the QED corrections to the energy levels. All values are given relative to the corresponding ground states. Final values that include QED corrections are given in columns "Total." The non-QED part of the calculation is the same as in $[7,8,52,53]$. The QED corrections are very significant for low-lying $4 f^{3}$ levels of Eu ${ }^{14+}$, so we have also included the CI + all-order values without QED for clarity. Table IV also includes the effective threeelectron ( $3 e$ ) interaction between valence electrons, recently treated in the framework of the CI + all-order approach in [56]. Our final results for $\mathrm{Ba}^{8+}$ are in excellent agreement
with experiment [57], demonstrating sub-\% accuracy of the theoretical energy levels.

In summary, we find that accurate treatment of the QED effects is essential for a reliable prediction of the transition energies in HCIs with optical transitions. The QED corrections in these ions are large enough to significantly affect the predictions of the transition wavelengths, but the correlation correction also has to be treated to high accuracy. Our results show that the QED corrections obtained by all four QED potentials are very similar, with the difference being smaller than the estimated uncertainty in the treatment of the correlation correction. We find that it is imperative to include the QED correction both in the construction of the basis set orbitals and into the CI Hamiltonian, in particular, for the configurations involving $5 f$ electrons, as in the example of Cf ion. This work also provides a revised value of the $\mathrm{Cf}^{15+}$ clock transition which has the highest enhancement of the $\alpha$ variation [8] in a system which also satisfies all criteria for the construction of the ultraprecise clock. Our method is generally applicable to treat any HCIs with up to four valence electrons.
